Planner

Important Note: Maximum document length is 3 pages.

1 Overview

This planner is mainly depending on the binary search trees, every binary search tree has a root, child, and leaf.

The root is the top node of the tree and is the key of entering the tree.

The child is every node that does not a root, and have at least one child.

The leaf is the node that does not have any children.

This planner supports five main operations: Add a new plan, modify an existing plan, find an existing plan, delete a plan, and print all the existing plans.

Root Greater Child Child Leaf Leaf

2 Main Flows

This code is divided into three files main.cpp, BST.cpp, and BST.h

As depicted in figure 2, is the BST.h file that has the main declaration of the class of the Binary Search tree and the functions used to implement the five operations of the planner.

The tree data is divided into 4 main categories, title is containing the title of the plan, key is the data stored in the tree, and this key contain the information of the day and the hour at the same time to reduce the complexity of the implementation I multiplied the day with 100 and added the value of the hour. (as example if the user entered 1 1 therefore the key value will be 101 and so on.), a pointer that points to the left of the tree, and one to the right.

Every function is having two version a public version that allows the user to interface with it, and a private function that has the main definition as an abstraction layer.

All what the public function do is to call the private function, and the private function will make what is desired.

The following figure 3 and 4 illustrate the main idea.
